Abstract This paper describes a new instance library for Quadratic Programming (QP). QP is a very "varied" class, comprising sub-classes of problems ranging from trivial to undecidable. Solution methods for QP are very diverse, ranging from entirely combinatorial ones to completely continuous ones, including many for which both aspects are fundamental. Selecting a set of instances of QP that is at the same time not overwhelmingly difficult and sufficiently challenging for the many different interested communities is therefore important. We propose a simple taxonomy for QP instances that leads to a systematic problem selection mechanism. We then briefly survey the field of QP, giving an overview of theory, methods and solvers. Finally we describe how the library was put together, and detail its final contents.

Keywords Instance Library, Quadratic Programming

Mathematics Subject Classification (2000) 90C06 · 90C25

1. Introduction

Quadratic Programming (QP) problems, where both the objective function and the constraints contain (at most) expressions in the variables of degree 2, contain a surprisingly diverse set of rather different problems. According to the fine details of the formulation, solving a QP may require employing either fundamentally combinatorial techniques, or ideas rooted in nonlinear optimization principles, or a mix of the two. In this sense, QP is likely one of the classes of problems where the collaboration between the communities interested in combinatorial and nonlinear optimization is more necessary, and potentially fruitful.

However, this diversity also implies that QP means very different things to different researchers. It is perhaps therefore not surprising that, unlike for "simpler" problems classes [6], so far there has never been a single library containing all different kinds of instances of QP. Several libraries devoted to special cases of QP are indeed available; however, each of them is either focussed on one application (a specific problem that can be modeled as QP), or on QPs with specific structural properties that make them suitable to be solved with some given class of algorithmic approaches. To the best of our knowledge, collecting a set of instances of QP that is at the same time not overwhelmingly numerous and significant for the many different interested communities has not been attempted, yet. This work constitutes a first step in this direction.

In this paper we report the steps that have been done to collect a (hopefully) significant library of QP instances, filtering the large set of available (or specifically provided) instances in order to end up with a manageable set that still contains a meaningful sample of all possible QP types. A particularly thorny issue in this process is how to select instances that are "interesting". Our solution is to take this to mean "challenging for a significant set of solution methods". Our filtering process has then been in part based on the idea that if a significant fraction of the solvers that can solve a QP instance do so in a "short" time, then the instance is not challenging enough to be included in the library. This also takes into account the fact that if very few (maybe one) solver can solve it very efficiently by exploiting some specific structure, but most other approaches cannot, then the instance can still be deemed "interesting". Putting this approach in practice requires a nontrivial number of technical steps and decisions that are detailed in the paper. We hope that our work can provide useful guidelines for other interested researchers.

A consequence of our focus is that this paper is *not* concerned about the different performance of the very diverse QP solvers; we will *not* report any data comparing them. The only reason why solvers are used (and, therefore, described) in this context is to ensure that the instances of the library are nontrivial at least for a significant fraction of the current solution methods; providing guidance about which solver is most suited to some specific class of QPs is entirely outside the scope of our work.

1.1 Motivation

TASK 2: write motivation

Optimization problems with quadratic constraints and/or objective function (QP) have been the subject of a considerable amount of research in the last decade. At least some of the rationale for this interest is likely due to the fact that they are the "least nonlinear nonlinear problems". Hence, in particular for the convex case, tools and techniques that have been honed during decades of research for Linear Programming (LP), typically with integrality constraints (MILP), can often be extended to the quadratic case with at least less effort than what would be required for tackling general Non Linear Programming (NLP) problems, without or with integrality constraints (MINLP). This has indeed happened over and over again with different algorithmic techniques, such as Interior Point methods, active-set methods (of which the simplex method is a prototypical example), enumeration methods, cut-generation techniques, reformulation techniques, and many others (citations?). Similarly, nonconvex continuous QP are perhaps the "simplest" class of problems that require features like spatial enumeration techniques to be solved. Hence, they are both the natural basis for the development of general techniques for nonconvex NLP, and a very specific class so that specialized approaches can be developed (citations, like copositive/standard QP?).

On the other hand, (MI)QP is, in some sense, a considerably more expressive class than (MI)LP. Quadratic expressions are found, either naturally or after appropriate reformulations, in very many practical problems (citations?). In general, any continuous function can be approximated with arbitrary accuracy (over a compact set) by a polynomial of arbitrary degree; in turn, every polynomial can be broken down to a system of quadratic expressions. Hence, (MI)QP is, in some sense, roughly as expressive as the whole of (MI)NLP. Of course this is, in principle, true for (MI)LP as well, but at the cost of much larger and much more complex formulations (citations?). Hence, for many applications QP may represent the "sweet spot" between the effectiveness, but lower expressive power, of (MI)LP and the higher expressive power, but much higher computational cost, of (MI)NLP.

. . .

The structure of this paper is the following. In §2 we review the basic notions about QP. In particular, §2.1 sets out the notation, §2.2 proposes a—to the best of our knowledge, new—taxonomy of QP that helps us in discussing the (very) different classes of QPs, §2.3 very briefly reviews the solution methods for QP upon which the solvers we have employed are based, and §2.4 describes the solvers. Then, §3 describes the process used to obtain the library and its results; the software tools that we have used, and that are freely released together with the library, are discussed in §4. Some conclusions are drawn in §5, after which in the Appendix a complete description of all the instances of the library is provided.

2. Quadratic Programming in a nutshell

2.1 Notation

In mathematical optimization, a Quadratic Program (QP) is an optimization problem in which either the objective function or some of the constraints are quadratic functions. More specifically, the problem has the form

$$\min \ x^{\top} Q^{0} x + L^{0} x$$

$$x^{\top} Q^{i} x + L^{i} x \leq C^{i} \qquad \qquad i \in \mathcal{M}$$

$$l_{j} \leq x_{j} \leq u_{j} \qquad \qquad j \in \mathcal{N}$$

$$x_{j} \in \mathbb{Z} \qquad \qquad j \in \mathcal{Z}$$

where:

- $-\mathcal{N} = \{1, \ldots, n\}$ is the set of (indices) of variables, and $\mathcal{M} = \{1, \ldots, m\}$ is the set of (indices) of constraints;
- $-x = [x_j]_{j=1}^n \in \mathbb{R}^n$ is a finite vector of real variables;
- $-Q^{i}$ for $i \in \{0\} \cup \mathcal{M}$ are symmetric $n \times n$ real matrices: because one is always only interested in the value of quadratic functions of the type $x^{\top}Q^{i}x$, symmetry can be assumed without loss of generality by just replacing both Q_{hk}^{i} and Q_{kh}^{i} with their average $(Q_{hk}^{i} + Q_{kh}^{i})/2$;

Ambros: I would use b^i instead of L^i and c^i instead of C^i (might avoid L vs. l confusion); plus capitals are often reserved for matrices)

- L^i and C^i for $i \in \{0\} \cup \mathcal{M}$ are, respectively, real *n*-vectors and real constants;

- $-\infty \leq l_j < u_j \leq \infty$ are the (extended) real upper and lower bounds on each variable x_j for $j \in \mathcal{N}$, assumed different because otherwise the variable is fixed;
- $-\mathcal{M} = \mathcal{Q} \cup \mathcal{L}$ where $Q^i = 0$ for all $i \in \mathcal{L}$ (i.e., these are the linear constraints, as opposed to the truly quadratic ones);
- the variables in $\mathcal{Z} \subseteq \mathcal{M}$ are restricted to only attain integer values.

Due to the presence of integral requirements on the variables, this class of problems is often referred to as Mixed-Integer Quadratic Program (MIQP). It will be sometimes useful to refer to the (sub)set $\mathcal{B} = \{i \in \mathcal{Z} : l_j = 0, u_j = 1\} \subseteq \mathcal{Z}$ of the binary variables, and to $\mathcal{R} = \mathcal{N} \setminus \mathcal{Z}$ as the set of continuous ones. Similarly, it will be sometimes useful to distinguish the (sub)set $\mathcal{X} = \{j : l_j > -\infty \lor u_j < \infty\}$ of the box-constrained variables from $\mathcal{U} = \mathcal{N} \setminus \mathcal{X}$ of the unconstrained ones (in the sense that finite bounds are not explicitly provided in the data of the problem, although they may be implied by the other constraints).

The relative flexibility offered by quadratic functions, as opposed e.g. to linear ones, allows several reformulation techniques to be applicable to this family of problems in order to emphasize different properties of the various components. Some of these reformulation techniques will be commented later on; here we remark that, for instance, integrality requirements, in particular in the form of binary variables could always be "hidden" by introducing (non convex) quadratic constraints utilizing the celebrated relationship $x_j \in \{0,1\} \iff x_j^2 = x_j$. Therefore, when discussing these problems an effort has to be made to distinguish between features that come from the original model, and those that can be introduced by reformulation techniques in order to extract (and algorithmically exploit) specific properties.

2.2 Classification

Despite the apparent simplicity of the definition given in §2.1, Quadratic Programming instances can be of several rather different "types" in practice, depending on the fine details of the data. In particular, many algorithmic approaches can only be applied to QP when the data of the problem has specific properties. A taxonomy of QP instances should therefore strive to identify the set of properties that an instance should have in order to apply the most relevant computational methods. However, the sheer number of different existing approaches, and the fact that new ones are proposed, makes it hard to provide a taxonomy that is both simple and covers all possible special cases. This is why, in this paper, we propose an approach that aims at finding a good balance between simplicity and coverage of the main families of computational methods.

2.2.1 Classification

Ambros:

OVC in-

stead of

FVC?

maybe

Our taxonomy is based on a three-fields code of the form "FVC", where F indicates the objective function, V the variables, and C the constraints of the problem. The fields can be given the following values:

objective function: (L)inear, (D)iagonal convex quadratic, (C)onvex quadratic, nonconvex (Q)uadratic;

- variables: (C)ontinuous only, (B)inary only, (M)ixed binary and continuous, (I)nteger only, (G)eneral (all threee types);
- constraints: (N)one, (B)ox, (L)inear, (C)onvex quadratic, nonconvex (Q)uadratic.

The wildcard "*" will be used to indicate any possible choice, and lists of the form "{X, Y, Z}" will indicate that the value of the given field can freely attain any of the specified values.

The ordering of the values in the previous lists is not irrelevant; in general, problems become "harder" when going from left to right. More specifically, for the F and C fields the order is that of strict containment between problem classes: for instance, Linear objective functions are strictly contained in Diagonal convex quadratic ones (by just allowing the diagonal elements to be all-zero), which are strictly contained into general Convex quadratic ones (by allowing the off-diagonal elements to be all-zero), which in turn are strictly contained into general nonconvex Quadratic ones (by allowing any symmetric Q^0 , hence possibly SDP ones as well). The only field for which the containment relationship is not a total order is V, for which only the partial orderings

$$C \subset M \subset G$$
 , $B \subset M \subset G$, $B \subset I \subset G$

hold. In the following discussion we will repeatedly exploit this by assuming that, unless otherwise mentioned, when a method can be applied to a given problem, it can be applied as well to all simpler problems where the value of each field is arbitrarily replaced with a value denoting a less general class.

2.2.2 Examples and reformulations

We will now provide a first general discussion about the different problem classes that our proposed taxonomy defines. Some of them are actually "too simple" to make sense in our context. For instance, D*B problems have only diagonal quadratic (hence separable) objective function and bound constraints; as such, they read

$$\min \left\{ \sum_{j \in \mathcal{N}} \left(Q_j^0 x_j^2 + L_j^0 x_j \right) : l_j \le x_j \le u_j \quad j \in \mathcal{N} , \ x_j \in \mathbb{Z} \quad j \in \mathcal{Z} \right\} .$$

Hence, their solution only requires the independent minimization of a convex quadratic univariate function in each single variable x_j over a box constraint and possibly integrality requirements: this can be attained trivially in O(1)

Ambros: maybe switch this with the next section? the next one contains more familiar material to the reader and might be an easier first introduction to the nota-

tion.

by closed-form formulæ, projection and rounding arguments. A fortiori, the even simpler cases L*B, D*N and L*N (the latter obviously unbounded unless $L^0=0$) will not be discussed here. Similarly, CCB (and, a fortiori, CCN) are immediately solved by linear algebra techniques, and therefore are of no interest in this context. On the other end of the spectrum, in general QP is a hard problem. Actually, LIQ—linear objective function and quadratic constraints in integer variables with no finite bounds, i.e.

$$\min \left\{ L^0x \ : \ x^\top Q^i x + L^i x \leq C^i \quad i \in \mathcal{M} \ , \ x_j \in \mathbb{Z} \quad j \in \mathcal{N} \right\} \ ,$$

is not only \mathcal{NP} -hard, but downright undecidable [5]. Hence so are the "harder" $\{C,Q\}IQ$.

It is important to note that the relationships between the different classes can be somehow blurred because reformulation techniques may allow to move one instance from one class to the other. The example in the introduction, for instance, says that *M*—instances with only binary and continuous variables—can be recast as *CQ: nonconvex quadratic constraints can always take the place of binary variables. Actually, this is also true for *G* as long as $\mathcal{U} = \emptyset$, as bounded general integer variables can be represented by binary ones.

Another relevant reformulation trick concerns the fact that, as soon as quadratic constraints are allowed, then a linear objective function can be assumed w.l.o.g.. Indeed, any Q** (C*C) problem can always be rewritten as

i.e., a L^*Q (L^*C). Hence, it is clear that quadratic constraints are, in a well-defined sense, the most general situation (cf. also the result above about hardness of LIQ).

When a Q^i is positive semidefinite (SDP), i.e., the corresponding constraint/objective function is convex, general quadratic constraints are in fact equivalent to diagonal ones. In fact, every SDP matrix can be factorized as $Q^i = L^i(L^i)^{\mathsf{T}}$,e.g. by the (incomplete) Cholesky factorization, $f^i(x) = x^{\mathsf{T}}Q^ix = \sum_{j \in \mathcal{N}} z_j^2 z$ where $z = x^{\mathsf{T}}L^i$. Hence, one could think that D** problems need not be distinguished from C** ones; however, this is true only for "complicated" constraints, but not for "simple" ones, because the above reformulation technique introduces linear constraints. Indeed, while C*L (and, a fortiori, C*{C,Q}) can always be brought to D*L (D*{C,Q}), using the same technique C*B becomes D*L, which is significantly different from D*B. In practice, a diagonal convex objective function under linear constraints is found in many applications (citations?), so that D*L still makes sense to distinguish the case where the objective function is "naturally" separable from

Ambros: did you really mean the same L^i as above?

that where separability is artificially introduced, although this is in theory always possible. Conversely, there is usually little gain in distinguishing between **C problems and "**D" ones where the constraints are restricted to be diagonal, as there are much fewer cases where this naturally occurs (to the best of my knowledge). This is why we did not include a "D" option for the constraints.

2.2.3 QP classes

The proposed taxonomy can then be used to describe the main classes of QP according to the type of algorithms that can be applied for their solution:

- Linear Programs LCL and Mixed-Integer Linear Programs LGL have been subject of an enormous amount of research and have their well-established instance libraries [6], so they won't be explicitly addressed here.
- Convex Continuous Quadratic Programs CCC can be solved in polynomial time by Interior-Point techniques; the simpler CCL can also be solved by means of "simplex-like" techniques (citations?). Actually, a slightly larger class of problems can be solved with Interior-Point methods: those that can be represented by Second-Order Cone Programs. When written as QPs the corresponding Qⁱ may not be positive semidefinite, but still the problems can be efficiently solved. Of course, these problems can still require considerable time, like LCL, when the size of the instance grows. In this sense, like in the linear case, a significant divide is from solvers that need all the data of QP to work, and those that are "matrix-free", i.e., only require the solution of simple operations (typically, matrix-vector products) with the data of the problem to work (citations?). While in our library we have never exploited such a characteristic, which is not suitable to the use of standard modeling tools, this may be relevant for the solution of very-large-scale CIC.
- Nonconvex Continuous Quadratic Programs QCQ are instead in general NP-hard, even if the constraints are very specific (QCB) and only one eigenvalue of Q⁰ is negative [4]. They therefore require enumerative techniques like the spatial Branch&Bound (citations?), to be solved to optimality. Of course, local approaches are available that are able to efficiently provide local optima (or at least saddle points) of the CQC, but providing global guarantees about the quality of the obtained solutions is challenging. In our library we have specifically focussed on exact solution of the instances.
- Convex Integer Quadratic Programs CGC are in general NP-hard, and therefore require enumerative techniques to be solved. However, convexity of the objective function and constraints implies that efficient techniques (see CCC) can be used at least to solve the continuous relaxation. The general view is that CGC are not, all other things being equal, substantially more difficult than LGL to solve, especially if the objective function and/or the constraints have specific properties (e.g., DGL, CGL). Often integer variables are in fact binary ones, so several CCC models are C{B,M}C

ones. In practice binary variables are considered to lead to somewhat easier problems than general integer ones (cf. the cited result about hardness of unbounded integer quadratic programs), and several algorithmic techniques have been specifically developed for this special case. However, the general approaches for CBC are basically the same as for CGC, so there is seldom the need to distinguish between the two classes as far as solvability is concerned, although matters can be different regarding actual solution cost. Programs with only binary variables CBC can be easier than mixed-binary or integer ones C{M,I}C because some techniques are specifically known for the binary-only case, cf. the next point (citations?). Absence of continuous variables, even in the presence of integer ones CIC, can also lead to specific techniques (citations??).

- Nonconvex Binary Quadratic Programs QB{B, N, L} obviously are NP-hard. However, the special nature of binary variables combined with quadratic forms allows for quite specific techniques to be developed, among which is the reformulation of the problem as a LBL. Also, many well-known combinatorial problems can be naturally reformulated as problems of this class, and therefore a considerable number of results have been obtained by exploiting specific properties of the set of constraints (some citations? some specific problem to mention apart from Max-Cut?).
- Nonconvex Integer Quadratic Programs QGQ is the more general, and therefore is the most general, class. Due to the lack of convexity even when integrality requirements are removed, solution methods must typically combine several algorithmic ideas, such as enumeration (distinguishing the role of integral variables from that of continuous ones involved into nonconvex terms) and techniques (e.g., outer approximation, SDP relaxation, ...) that allow to efficiently compute bounds. As in the convex case, QBQ, QMQ, and QIQ can benefit from more specific properties of the variables (citations?).

This description is purposely coarse; each of these classes can be subdivided into several other ones on the grounds of more detailed information about structures present in their constraints/objective function. These can have a significant algorithmic impact, and therefore can be of interest to researchers. Common structures are, e.g., network flow or knapsack-type linear constraints, semi-continuous variables, or the fact that a nonconvex quadratic objective function/constraint can be reformulated as a second-order cone (hence, convex) one. It would be rather hard to collect a comprehensive list of all types of structures that may be of interest of some researcher, since these are as varied as the different possible approaches for specialized sub-classes of QP. For this reason we do not attempt such a more refined classification, and limit ourselves to the coarser one described in this paragraph.

2.3 Solution Methods

In this section we provide a quick overview of existing solution methods for QP, restricting ourselves to these implemented by the set of solvers considered in this paper (Table 1). For each approach we briefly describe the main algorithmic ideas and point out the formulation they address according to the classification set out in Sect. 2.2. We remark that many solvers implement more than one algorithm, among which the user can choose at runtime. Moreover, algorithms are typically implemented by different solvers in different ways, so that the same conceptual algorithm can sometimes yield wildly different results or performance measures on the same instances.

The methods implemented by the solvers in Table 1 can, following [9], be broadly organized in three categories: incomplete, asymptotically complete, and complete. Incomplete methods are only able to identify solutions, often locally optimal according to a suitable notion, and may even fail to find one even when one exists; in particular, they are typically not able to determine that an instance is empty. Asymptotically complete methods can find a globally optimal solution with probability one in infinite time, but again they cannot prove that a given instance is infeasible. Complete methods find an approximate globally optimal solution to within a prescribed optimality tolerance within finite time, or prove that none such exists (but see Sect. 2.3.3 below); they are often referred to as exact methods in the computational optimization community. According to [9], rigorous methods also exist which find global within given tolerances even in the presence of rounding errors, except in "near-degenerate cases". Since it is debatable whether any of the solver we are using can be classified as rigorous, we have elected to limit ourselves to declaring solvers complete.

Incomplete methods are usually realized as local search algorithms, asymptotically complete methods are usually realized by meta-heuristic methods such as multi-start or simulated annealing, and complete methods for \mathcal{NP} -hard problems such as QP are typically realized as implicit exhaustive exploration algorithms. However, these three categories may exhibit some overlap. For example, any deterministic method for solving QCQ locally is incomplete in general, but becomes complete for CCC, since any local optimum of a convex QP is also global. Therefore, when we state that a given algorithm is incomplete or (asymptotically) complete we mean that it is so the largest problem class that the solver naturally targets, although it may be complete on specific sub-classes. For example, SNOPT naturally targets continuous nonconvex NLPs and it is incomplete on this class, and therefore on QCQ, but becomes complete for CCC. In general, all complete methods for a problem P must be complete for any problem $Q \subseteq P$, while a complete method for P might be incomplete for $R \supset P$.

2.3.1 Incomplete methods

Local search methods typically require as an input a solution x' and attempt to improve it—either towards feasibility, or towards optimality, or both—using only information that is available in a neighborhood of x'. In general, local search methods are incomplete. As remarked above, however, local search methods deployed on a convex problem behave like complete methods, possibly via devices that that allow to find a feasible starting solution if there is one (the so-called "phase 0").

Most local search methods for *C* are iterative in nature, and need a feasible starting point x^0 as input. The (k+1)-st iterate is obtained as $x^{k+1} = x^k + \alpha_k d^k$, where α_k (a scalar) is the *step length*, and d^k (a vector) is the *search direction*, e.g. belonging to a tangent manifold and having a negative directional derivative at x^k , in order to improving optimality while reducing infeasibility. Local search methods for *I* are also iterative, but since defining a useful notion of descent direction is harder in presence of integer variables, d^k and α_k are usually computed in different ways, depending on the application at hand.

The solvers in Table 1 which implement incomplete methods are CONOPT, IPOPT, MINOS, SNOPT and KNITRO. The former four solvers implement local search algorithms for continuous nonconvex NLPs (a problem class containing QCQ). Note that traditionally KNITRO used to be a local (nonconvex) NLP solver. All of these solvers implement essentially two types of local search methods for NLP:

- active set methods (CONOPT, MINOS, SNOPT);
- interior point methods (IPOPT, KNITRO).

Active set and interior point methods have been defined for *C* but also for general (continuous) NLPs. In fact, all of the solvers named above target this larger problem class.

Active set methods. At each iteration k the algorithm forms the active set \mathcal{A}^k containing the (indices of the) active constraints, i.e., all of the equality constraints as well as the inequality constraints that are satisfied at equality at the current iterate x^k . A subproblem, consisting of a minimization of a certain auxiliary objective function subject to all active constraints, is then solved to identify a good search direction d^k . An appropriate step length α_k is then found by checking for the inactive constraints (since these must be satisfied too). If at x^{k+1} some of the previously inactive constraints have become active, or vice versa, \mathcal{A}^k is updated accordingly. This general scheme works because the subproblem is defined in such a way as to be (a) easier to solve than the original problem, and (b) helping the sequence x^k to converge to a Karush-Kuhn-Tucker (KKT) point.

Interior point methods. These approaches can be seen as recasting the original constrained problem QP as a parametrized family of unconstrained ones

 QP_{μ} , where the constraints are moved in the objective function via a barrier term—that goes to $+\infty$ as the boundary of the feasible region is approached weighted with the barrier parameter $\mu \in (0, \infty)$. In the convex case, the central path—the continuous line formed from the optimal solutions of QP_{μ} for all varying μ , typically unique e.g. if the classical barrier based on the logarithmic function is employed—leads to a (central) optimal solution of QP when $\mu \to 0$. Starting from an appropriately constructed "central" point (close to the solution of QP_{μ} for "large" μ), these algorithms strive to follow the central path by performing O(1) Newton steps before (substantially) reducing μ . The algorithms can be shown to converge in a small number of iterations, each of which can be costly due to the need of solving an appropriately modified version of the KKT conditions for QP ("slackened" with μ), a (possibly) large-scale linear system. Actually, nowadays the algorithm is most often implemented in the primal-dual version, where the nonlinear KKT system is iteratively solved with Newton-like iterations; this has the extra advantage of allowing to remove the need of a feasible (central) starting point.

2.3.2 Asymptotically complete methods

Asymptotically complete methods do not usually require a starting point, and, if given sufficient time (infinite in the worst case) will identify a globally optimal solution with probability one. Most often, these methods are meta-heuristics, involving an element of random choice, which exploit a given (heuristic) local search procedure.

The solvers in Table 1 which implement asymptotically complete methods are OQNLP, MSNLP and certain sub-solvers of LGO. Specifically, we consider the following methods:

- global adaptive random search (LGO_GARS);
- multi-start (LGO_MS, MSNLP, OQNLP); specifically, the former two apply to QCQ whereas the latter to QGQ.

Global Adaptive Random Search. This is a modification of an algorithm called pure random search, which consists in sampling a random point x' from a given compact set known to contain a global optimum, and then sampling a new candidate solution y in a neighborhood of x', setting $x' \leftarrow y$ if y improves x', and repeating as long as a termination condition is not satisfied. The adaptivity stems from changing the distribution for sampling y at run-time, depending on the quality of the solutions identified by the method. Since this method only depends on sampling and function evaluation, it is usually fast. In the LGO_GARS solver, it provides a useful starting point for a subsequent local search procedure. Asymptotic global convergence is attained by restarting the random search from different initial points x'.

Multi-start. Multi-start methods define a loop around a given local search procedure so that it starts from many different starting points, perform local

search, and record the best optimum found so far as they explore the search space randomly. For example, any of the methods described in Sect. 2.3.1 can be embedded in a multi-start framework as follows:

- 1. initialize a "best solution so far" x^*
- 2. sample a starting point x' uniformly at random from a given compact set known to contain a global optimum;
- 3. run a local search method from x' to yield an improved (feasible) point x
- 4. if x improves on x^* with respect to the objective function value, replace x^* with x
- 5. repeat from Step 2 until a given termination condition is satisfied.

The method is asymptotically complete if the termination condition in Step 2 is a certificate of global optimality for x^* , which is usually hard to obtain. However, typically some bound on the total CPU time, or number of function evaluations, or any other criteria that makes sense for the application at hand, is needed, which renders the method incomplete.

In general, the applicability of meta-heuristics to a given problem depends on whether the local search they utilize addresses that problem or not. Antonio: the concept of "addresses that problem" is not very clear to me, this sentence may benefit from rephrasing (or the paragraph from deleting if it's not deemed to be utterly necessary). Depending on the local search employed, Multi-start methods can address MINLP of the most general class.

2.3.3 Complete methods

Complete methods are often referred to as exact in a large part of the mathematical optimization community. This nomenclature has to be used with care, as it implicitly makes assumptions on the underlying computational model that may not be acceptable in all cases. To see that, consider that, as already mentioned, QPs (more precisely, LIQ) are generally undecidable [5]; and yet, there exists a general decision method for deciding feasibility of systems of polynomial equations and inequalities [11], including the solution of LCQ with zero objective function. This apparent contradiction is due to the fact that the two statements refer to different computational models: the former is based on the Turing Machine (TM), whereas the latter is based on the Real RAM (RRAM) machine [3]. Due to the potentially infinite nature of exact real arithmetic computations, exact computations on the RRAM necessarily end up being approximate on the TM. Analogously, a complete method may reasonably be called "exact" on a RRAM; however, the computers we use in practice are more akin to TMs than RRAMs, and therefore calling exact a solver that employs floating point computations is, technically speaking, stretching the meaning of the word. However, because the term is well understood in the computational optimization community, in the following we shall loosen the distinction between complete and exact methods, with either properties intended to mean "complete" in the sense of [9].

Branch-and-Bound. Nearly all of the complete solvers in Table 1 that address \mathcal{NP} -hard problems (i.e. those in QGQ \setminus CCC) are based on Branch-and-Bound (BB). This is an implicit but exhaustive search process based on exploring a branching tree of the problem, where each node in the tree represents a subset of the feasible region. Guaranteed lower and upper bounds to the objective function value relative to nodes are computed in various ways. Nodes are discarded when: (a) they can be shown to be empty; (b) their bound in the optimization direction is worse than an opposite global bound; (c) a global optimum limited to the node can be found (this happens when the two bounds are closer than a given ε tolerance); (d) they are selected for branching, which means expanding the tree constructing at least two new nodes, children of the current one. Branching takes place by identifying one or more branching directions, which are usually a coordinate axes, and one or more branching point per direction, in various common sense fashions. The algorithm is driven by a queue of active nodes, usually endowed with a priority to select the most promising node from which to continue exploration of the tree (such as "most promising bound"); the BB algorithm terminates when the queue is empty.

Typically, bounds in the optimization direction are computed by means of convex relaxations [7,1], which replace nonconvex terms t(x) with linearization variables \hat{t} , and then replace the corresponding defining constraints $\hat{t} = t(x)$ by means of lower and upper (respectively, convex and concave) bounding functions $\hat{t} \geq \underline{t}(x)$ and $\hat{t} \leq \overline{t}(x)$. This is actually where finite (and tight) bounds on the variables are crucial, which differentiate also in practice the bounded case from the unbounded one. Different strategies are used when the nonconvexities are only quadratic [8,2].

When the BB algorithm is allowed to select coordinate directions corresponding to continuous variables, it is called *spatial* BB (sBB). Branching on continuous (rather than integer or binary) variables becomes necessary in the presence of nonconvex nonlinearities, as it happens e.g. in QCQ, since the quality of the bounds improves as the feasible set in the current node gets smaller.

BB algorithms are exponential time in the worst case, and their exponential behavior unfortunately often shows up in practice. They can also be used heuristically (forsaking their completeness guarantee) by either terminating them early, or by using non-guaranteed bounds.

The solvers in Table 1 BB type methods are:

- Antigone, Baron, Couenne, Lindo, LindoGlobal, SCIP, Lgo_bb, which implement complete BB algorithms for QGQ;
- CPLEX, which implements a complete BB algorithm for QGL;
- KNITRO_BB, BONMIN, sBB, XPRESS, GUROBI, which implement complete BB algorithms for CGC. how about MOSEK?

We remark that the latter category can be used as incomplete solvers for QGQ. We also remark that CPLEX can currently only target problems with linear constraints when the objective function is nonconvex [2].

Table 1 Families of QP problems that can be tackled each solver

Cutting plane approaches . The two remaining solvers in Table 1 are Alphaecp [12] and DICOPT [10], which are complete cutting plane methods based on different principles. Characteristic of both solvers is that they need to employ a complete method for solving MILP (LIL) sub-problems at each iteration; in turn, this is typically based on BB, which is therefore a crucial technique also for this class of approaches. Additionally, incomplete methods can be used to provide local solutions. Other solvers, like Bonmin, also offer this kind of approach among their algorithmic options.

2.4 Solvers

We now provide a succinct list of the solvers we have tested, using the approaches described in §2.3. In Table 1, we mark with "I" a pair (solver, problem) if the solver accepts the problem in input but it is an incomplete solver for the problem, with "A" if it is asymptotically complete, with "C" if it is complete, and leave it blank if the solver won't accept the problem in input.

The table has to be checked, as I've extrapolated from the text but I'm not 100% sure. Also, "?"s have to be removed.

Ambros: merge with Section 2.3.3 or put list of solvers in Section 2.3.3 here

3. Library Construction

In this section we present all the steps performed in order to build the library. In particular we describe the first set of gathered instances (Section 3.1), we discuss the issues concerning the format of the instances (Section 3.2), we

Table 2 Instance filter steps

present the feature used to classified the instances (Section 3.3), and finally we then describe the selection process that we have used to filter the instances in order to construct the final library (Section 3.4).

3.1 Instance Collection

In this section we describe the procedure we adopted to gather the instances. In January 2014, we issued an online call for instances to the main international mailing lists of the mathematical optimization and numerical analysis community, in order to reach the largest possible set of interested researchers, both in academia and in industry. The call remained open for 10 months, during which we received a large number of contributions with different characteristics. The instances we received are both artificial and coming from real-world applications.

In addition to spontaneous contribution we scanned the other known libraries of instances and we selected all the QP ones. In particular we cite here the libraries of "generic" QP instances from which we draw material:

- POLIP http://polip.zib.de/pipformat.php
- MINLP http://www.gamsworld.org/minlp/minlplib.htm
- $\ {\tt MacMINLP\ https://wiki.mcs.anl.gov/leyffer/index.php/MacMINLP}$
- Meszaros http://www.doc.ic.ac.uk/~im/OOREADME.QP
- BARON Library http://www.minlp.com/nlp-and-minlp-test-problems
- GAMS Library http://www.gamsworld.org/performance/performlib.htm

Other QP instances were found in libraries devoted to specific optimization problems that can be modeled as QP, such as Max-Cut, the Quadratic Assignment Problem, Portfolio Optimization problems and several others; for reason of space we refrain from listing all these sources.

At the end of this process we had gathered more than eight thousand instances. Three fourths of them contained discrete variables, while the remaining ones contained only continuous variables.

First Instances Filter. As already mentioned an important characteristic of an instances is its computational difficulty, i.e., the CPU time needed by a complete solver (cf. §2.3) to solve the instance to global optimality. Accordingly,

Obj. Fun.	Variables	Constraints	#
	Binary	Quadratic	71
	Mixed	Convex	5
	Mixed	Quadratic	277
Linear	General	Convex	22
	General	Quadratic	8
	Binary	Linear	12
Convex	Mixed	Linear	37
Convex	Mixed	Quadratic	3
	General	Linear	1
		None	29
	Binary	Linear	180
	Mixed	Linear	12
Quadratic	Mixed	Quadratic	9
	Integer	Linear	2
	General	Linear	1
	General	Quadratic	2
Total			600

Table 3 Classification of the final set of discrete instances

for each of the gathered instance we run the solvers in GAMS (see Table ??) able to solve it to global optimality. The number of solvers depends on the category of the instances under consideration. Then in order to reduce the number of instances we performed a first filter based on a relative measure of computational difficulty, i.e., we discarded all "easy" instances which are solved by at least 30% of the complete solvers within a time limit of 30 seconds. Thanks to this first filter we obtained what we call the *filtered test bed*.

The characteristics of the instances in the final library are presented in Table 3.1 for *discrete* instances (*{B,M,I,G}*) and in Table 3.1 for *continuous* ones (*C*).

3.2 Instance Format

TASK X: write In the call for instances no specific formats were imposed for the submissions. To evaluate the instances we decided, for practical reasons, to use GAMS as common platform for all the experiments involving commercial solvers. For this reason, we decided to translate all instances into the .gms gams format. In a preliminary phase, all the instances received were divided according to their format and subsequently translated. In Sect. the tools used to translate an instance from a given format to the .gms format are described more in detail.

Obj. Fun.	Constraints	#
Linear	Convex	14
Linear	Quadratic	71
	None	6
Convex	Box	6
	Linear	50
	Convex	3
	Quadratic	6
	Box	8
Quadratic	Linear	19
	Convex	27
	Quadratic	40
Total		250

Table 4 Classification of the final set of continuous instances

As second format, we introduced a specific format .qplib. This new format is capable to describe all the instances of the library in a sparse form. In comparison to a more *high level* format like .gms, the new format presents two advantages: it is easier to read by a self-made parser and it produces smaller files. ToDo: describe .qplib format. Maybe in an appendix?

3.3 Instance Features

TASK X : write

For each instance of the starting set, the following features have been collected:

- Objective function characteristics:
 - Type of objective function: Linear, Convex or Quadratic.
 - Density of the objective function, i.e. the percentage of nonzero entries of Q_0 .
 - Percentage of negative eigenvalues of Q_0 .
- Variables characteristics:
 - Number of Continuous, Binary and Integer variables.
- Constraints characteristics:
 - Number of Linear, Convex and Quadratic constraints.
 - Density of the constraints, i.e. the percentage of nonzero entries of the coefficients of the Linear, Continuous and Quadratic constraints.

The mentioned features

- constraint-types: big-M constraints? box-constraints? combinatorial constraints? linear network?
- nonconvex: whether they can be turned into cones through appropriate decomposition
- quadratic: are discrete variables contained in the quadratic part or in the linear part only?

- note: some remark like "max-cut", "quadratic knapsack", etc.

Solver-dependent characteristics:

- time (?) [how measure time? what architecture will be used for tests? how to deal with parallel machines/algorithms?]
- number of nodes in case of branch-and-bound algorithms
- memory (?)
- matrix-free access (?)
- lower bound at root node
- time of finding first feasible solution
- The static analysis is not enough to identify the hardness of the instances.
- An empirical way for testing the hardness of one instance is the time needed to solve it.
- We decided to use a broad set of solvers to test the computational hardness of the instances.
- 3.4 Instance Selection

TASK X : write

4. Software tools

4.1 instance translator

GAMS-LP-QPFORMAT TASK X : write

4.2 code that computes the features of an instance

TASK X : write

4.3 code that selects subsets of instances

TASK X : write

4.4 website, instance collector

4.5 testing environment

RUN GAMS USING A SUBSET OF SOLVERS TASK X : write

Appendix

In this Appendix we provide detailed data on all the instances of the final library. This is done in Tables 6–6 for discrete instances (*{B,M,I,G}*) and in Tables 6–6 for continuous ones (*C*). In the former, the features of the instances are described by three sets of columns. The first ("% eig") describes the objective function by reporting the fraction of eigenvalues of Q^0 that are negative: a positive number implies that Q^0 is not SDP (hence, the instance is a Q**), "0.000" implies that Q^0 is SDP (hence, the instance is a C**), a blank implies that Q^0 = 0, i.e., the objective function is linear (hence, the instance is a L**). The following three columns describe the variables by reporting the number of binary ones ("# bin"), general integer ones ("# int"), and continuous ones ("# cont"). Finally, the last three columns describe the constraints reporting the number of linear ones ("# lin"), nonconvex quadratic ones ("# quad"), and convex quadratic ones ("# conv"). Tables 6–6 are similarly structured except that all variables are continuous, and hence only one column is present.
